BACKGROUND

[0001] Signal distortion limits the sensitivity and bandwidth of any communication system. A form of distortion commonly referred to as "intersymbol interference" (ISI) is particularly problematic and is manifested in the temporal spreading and consequent overlapping of individual pulses, or "symbols." Severe ISI prevents receivers from distinguishing symbols and consequently disrupts the integrity of received signals.

[0002] Figure 1 (prior art) depicts a conventional receiver 100, which is used here to illustrate the ISI problem and a corresponding solution. Receiver 100 includes a data sampler 105 and a feedback circuit 110. Sampler 105 includes a differential amplifier 115 connected to a decision circuit 120. Decision circuit 120 periodically determines the probable value of signal D_{in} and, based on this determination, produces a corresponding output signal D_{out} .

[0003] Sampler 105 determines the probable value of signal D_{in} by comparing the input signal D_{in} to a voltage reference V_{ref} at a precise instant. Unfortunately, the effects of ISI depend partly on the transmitted data pattern, so the voltage level used to express a given logic level varies with historical data patterns. For example, a series of logic zero signals followed by a logic one signal produces different ISI effects than a series of alternating ones and zeroes. Feedback circuit 110 addresses this problem using a technique known as Decision Feedback Equalization (DFE), which produces a corrective feedback signal that is a function of received

historical data patterns.

[0004] DFE feedback circuit 110 includes a shift register 125 connected to the inverting input of amplifier 115 via a resistor ladder circuit 130. In operation, receiver 100 receives a series of data symbols on an input terminal Din, the non-inverting input terminal of amplifier 115. The resulting output data Dout from sampler 105 is fed back to shift register 125, which stores the prior three output data bits. (As with other designations herein, Din and Dout refer to both signals and their corresponding nodes; whether a given designation refers to a signal or a node will be clear from the context.)

[0005] Shift register 125 includes a number of delay elements, three flip-flops D1-D3 in this example, that apply historical data bits to the reference voltage side of the differential amplifier 115 via respective resistors R1, R2, and R3. The value of each resistor is selected to provide appropriate weight for the expected effect of the corresponding historical bit. In this example, the value of resistor R3 is high relative to the value of resistor R1 because the effect of the older data (D3) is assumed to be smaller than the effect of the newer data (D1). For the same reason, the resistance of resistor R2 is between the resistors R1 and R3. Receiver 100 includes a relatively simple DFE circuit for ease of illustration: practical DFE circuits may sample more or fewer historical data values. For a more detailed discussion of a number of receivers and DFE circuits, see U.S. Patent No. 6,493,394 to Tamura et al., issued December 10, 2002, which is incorporated herein by reference.

[0006] The importance of accurate data reception motivates receiver manufacturers to characterize carefully their system's ability to tolerate ISI and other types of noise. One such test, a so-called "margin" test, explores the range of

voltage and timing values for which a given receiver will properly recover input data.

[0007] Figure 2 depicts a fictional eye pattern 200 representing binary input data to a conventional receiver. Eye pattern 200 is graphed in two dimensions, voltage V and time T. The area of eye 205 represents a range of reference voltages and timing parameters within which the data represented by eye 205 will be captured. The degree to which the voltage V and time T of the sampling point can vary without introducing an error is termed the "margin."

[0008] Figures 3A through 3C depict three signal eyes 300, 305, and 310 illustrating the effects of DFE on margins and margin testing. Referring first to Figure 3A, eye 300 approximates the shape of eye 205 of Figure 2 and represents the margin of an illustrative receiver in the absence of DFE. Figure 3B represents the expanded margin of the same illustrative receiver adapted to include DFE: the DFE reduces the receiver's ISI, and so extends the margins beyond the boundaries of eye 300. Increasing the margins advantageously reduces noise sensitivity and improves bit error rates (BER).

[0009] In-system margin tests for a receiver are performed by monitoring receiver output data (e.g., Dout in Figure 1) while varying the reference voltage and sample timing applied to the input waveform Din. With reference to Figure 2, such testing samples various combinations of voltage and time to probe the boundaries of eye 205, the boundaries being indicated when the output data does not match the input data. Margin tests thus require the receipt of erroneous data to identify signal margins. Zerbe et al. detail a number of margin tests in "Method and Apparatus for Evaluating and Optimizing a Signaling System," U.S. Patent Application Serial No. 09/776,550, which is incorporated herein by reference.

[0010] A particular difficulty arises when determining the

margins of DFE-equipped receivers. While feeding back prior data bits increases the margin (Figure 3B), the effect is just the opposite if the feedback data is erroneous. Erroneous feedback emphasizes the ISI and consequently reduces the margin, as shown in Figure 3C. The margin of a DFE-equipped receiver thus collapses when a margin test begins to probe the limits of the test signal (e.g., the boundaries of eye 205). The incompatible requirements of erroneous data for the margin test and correct data for the DFE thus impede margin testing. There is therefore a need for improved means of margin testing DFE-equipped receivers.

[0011] The need for accurate margin testing is not limited to DFE-equipped receivers. Errors in margin testing lead integrated-circuit (IC) designers to specify relatively large margins of error, or "guard bands," to ensure that their circuits will perform as advertised. Unfortunately, the use of overly large margins reduces performance, an obvious disadvantage in an industry where performance is paramount. There is therefore a need for ever more precise methods and circuits for accurately characterizing the margins of high-speed integrated circuits.

SUMMARY

[0012] The present disclosure is directed to methods and circuits for margin testing high-speed receivers. Some embodiments equipped with Decision Feedback Equalization (DFE) or other forms of feedback that employ historical data to reduce inter-symbol interference (ISI) perform margin tests using a known input data stream. The receiver injects a copy of the known input data stream (i.e., the "expected data") into the feedback path irrespective of whether the receiver correctly interprets the input data. The margins are therefore maintained in the presence of receiver errors,

allowing in-system margin tests to probe the margin boundaries without collapsing the margin. Receivers in accordance with some embodiments include local sources of expected data.

[0013] Other embodiments do not rely on "expected data," but can be margin tested in the presence of any pattern of received data. These embodiments are particularly useful for in-system margin testing. Also important, such systems can be adapted to dynamically alter system parameters during device operation to maintain adequate margins despite fluctuations in the system noise environment due to e.g. temperature and supply-voltage changes.

[0014] Also described are methods of plotting and interpreting error data generated by the disclosed methods and circuits. One embodiment generates shmoo plots graphically depicting the results of margin tests. Some embodiments filter error data to facilitate pattern-specific margin testing.

[0015] This summary does not limit the invention, which is instead defined by the allowed claims.

BRIEF DESCRIPTION OF THE FIGURES

[0016] Figure 1 (prior art) depicts a conventional digital receiver 100.

[0017] Figure 2 depicts a fictional eye pattern 200 representing binary input data to a conventional receiver.

[0018] Figures 3A through 3C depict three signal eyes 300, 305, and 310 illustrating the effects of DFE on margins and margin testing.

[0019] Figure 4 depicts a communication system 400, including a conventional transmitter 402 connected to a DFE-equipped receiver 403 adapted in accordance with one embodiment.

[0020] Figure 5 depicts a DFE-equipped receiver 500 adapted in accordance with an embodiment to include improved means of

margin testing.

[0021] Figure 6 depicts a receiver 600 in accordance with another embodiment.

[0022] Figure 7 depicts a receiver 700 in accordance with yet another embodiment.

[0023] Figure 8 depicts an embodiment of a buffer 800, which may be used as one of amplifiers 745 in weighting circuit 735 of Figure 7.

[0024] Figure 9 depicts a receiver 900 in accordance with another embodiment.

[0025] Figure 10A depicts a receiver 1000, a simplified version of receiver 900 of Figure 9 used to illustrate margin mapping in accordance with one embodiment.

[0026] Figure 10B is a diagram illustrating the relationship between each of samplers 1005 and 1010 of Figure 10A and a data eye 1030.

[0027] Figure 10C depicts a shmoo plot 1050 graphically depicting an illustrative margin test in accordance with one embodiment.

[0028] Figure 11 details an embodiment of shmoo circuit 1025 of Figure 10A.

[0029] Figure 12 details a receiver 1200 in accordance with another embodiment adapted to accommodate margin shmooing.

[0030] Figure 13 depicts a receiver 1300 that supports error filtering in accordance with another embodiment.

DETAILED DESCRIPTION

[0031] Figure 4 depicts a communication system 400, including a conventional transmitter 402 connected to a receiver (receive circuit) 403 equipped with Decision Feedback Equalization (DFE). In a normal operational mode, receiver 403 samples an input data stream from transmitter 402. The sampled data provides DFE feedback to reduce intersymbol

interference (ISI). In a margin-test mode, receiver 403 samples a known input data stream using ranges of sample timing and reference voltages. To prevent a collapse of the margins, the DFE feedback path disregards the potentially erroneous sampled data in favor of an identical version of the known input data stream. In-system margin tests can therefore probe the margin without collapsing the margin limits.

[0032] Receiver 403 conventionally includes a sampler 405, an optional clock-and-data recovery (CDR) circuit 410, and a DFE circuit 415. During normal operation, receiver 403 receives a data stream (e.g., a series of data symbols) on sampler input terminal Din. Sampler 405 samples the data stream using a recovered clock RCK from CDR circuit 410 and produces the resulting sampled data stream on a sampler output terminal Dout. DFE circuit 415 stores a plurality of prior data samples and uses these to condition the input data in the manner discussed above in connection with Figure 1. In addition to the conventional components, receiver 403 includes a multiplexer 420, an expected-data source 425, and some comparison logic 430, in this case an exclusive OR (XOR) gate.

[0033] During normal operation, a test control signal T to multiplexer 420 is set to a logic zero to connect the output data Dout to the input of DFE 415. Thus configured, receiver 403 acts as a conventional DFE-equipped receiver. In a margin-test mode, however, select signal T is set to a logic one so as to convey an expected data stream from data source 425 to the input of DFE 415. Transmitter 402 then supplies known test data on terminal Din while the expected data is applied to DFE 415. The expected data is an identical, time-shifted version of the known data applied to input terminal Din, so DFE 415 produces the correct feedback without regard to the output signal Dout. In essence, multiplexer 420 provides the feedback path with a first input terminal for

sampled output data in the operational mode and with a second input terminal for expected data in the margin-test mode.

[0034] The repeated reference herein to "terminal" Din, as opposed to the plural form "terminals," is for brevity. Receivers may include more than one data-input terminal, such as those that rely upon differential signaling. Likewise, other clock, reference, and signal paths noted herein can be single-ended, differential, etc., as will be evident to those of skill in the art. The preferred manner in which particular test circuits and methods are adapted for use with a given receiver will depend, in part, on the receiver architecture.

[0035] A voltage control signal CV on a like-named sampler input terminal alters the reference voltage used by sampler 405 to sample input data. A clock control signal CC to CDR circuit 410 modifies the timing of recovered clock signal RCK. Control signals CV and CC are used in margin testing to explore the voltage and timing margins of receiver 403. When the margin tests reach the margin limits, and thus introduce errors in output signal Dout, expected-data source 425 continues to provide the correct DFE feedback signal and consequently prevents the margins from collapsing in response to the errors. Comparison circuit 430 monitors the sampled-data series for errors by comparing the output data with the expected data from expected-data source 425. In the event of a mismatch, comparison circuit 430 produces a logic one error signal ERR. A sequential storage element (not shown) captures any error signal. Receiver 403 thus facilitates margin testing of DFE-equipped receivers without collapsing the margin of interest. (Error signal ERR may or may not be monitored in the operational mode.)

[0036] Expected-data source 425 produces the same data as expected on input terminal Din. Source 425 can be a register in which is previously stored a known data pattern to be

provided during margin testing. Source 425 might also be a register that goes through an expected sequence of data, such as a counter or a linear-feedback shift register (LFSR). Regardless of the source, the expected data presents the expected output data, appropriately timed, to the input of the feedback circuit DFE 415.

[0037] Figure 5 depicts a receiver circuit 500 in accordance with another embodiment. Receiver 500 is similar in some ways to receiver 403 of Figure 4, like-numbered elements being the same. Receiver 500 is extended to include a second sampler 505 that is substantially identical to, and consequently mimics the behavior of, sampler 405. The margin tests are performed on replica sampler 505 so that margin-testing circuitry has little or no impact on the performance of receiver 500 in the operational mode.

[0038] Receiver 500 includes a multiplexer 510 connected to a shift register 515. A modified clock and data recovery circuit CDR 520 controls the timing of both samplers 505 and 405. The timing control terminal is omitted for brevity.

[0039] Prior to a margin test, test signal T is set to logic zero and the storage elements within register 515 are loaded with an expected-data sequence. Then, in the test mode, test terminal T is set to logic one so that shift register 515 feeds its output back to its input via multiplexer 510. To perform a margin test, sampler 505 samples input data Din. Comparison circuit 430 compares the resulting samples with the expected-data sequence provided by the first storage element in register 515. Any difference between the data sampled by the replica sampler 505 and the expected sequence from register 515 induces comparison circuit 430 to produce a logic one error signal on line ERR. Clocking circuitry, e.g. within CDR 520, can be adapted to control separately the recovered clock signals RCK1 and RCK2.

[0040] Figure 6 depicts a receiver 600 in accordance with another embodiment. Receiver 600 is similar to the conventional receiver 100 of Figure 1, but is modified to support improved margin testing.

[0041] Receiver 600 includes a sampler 602 that, like sampler 105 of Figure 1, includes a differential amplifier 115 and a decision circuit 120. Although not shown, sampler 602 includes conventional means of adjusting the reference voltage and timing to support margin testing. DFE of receiver 600 performs conventionally in the operational mode and provides expected data in the margin-test mode.

[0042] Receiver 600 includes a multiplexer 605, a comparison circuit 610, and a dual-mode register 615. Multiplexer 605 conveys output signal Dout to register 615 in the operational mode. Thus configured, receiver 600 functions analogously to receiver 100 of Figure 1. That is, register 615 shifts in the output data Dout and employs three bits of historic data to provide ISI-minimizing feedback to sampler 602.

[0043] During margin testing, test signal T is set to logic one. In that case, multiplexer 605 provides the output of an XOR gate 620 to the input of register 615. The inclusion of XOR gate 620 and the path through multiplexer 605 converts register 615 into a linear-feedback shift register (LFSR) that provides a pseudo-random but deterministic sequence of bits to both the input of register 615 and comparison circuit 610. Also during the margin test, the same pseudo-random sequence produced by register 615 is provided on input terminal Din. This test sequence is applied one clock cycle ahead of the expected data in flip-flop D1 of register 615, so the DFE will reflect the appropriate data regardless of whether output data Dout is correct. The timing and reference voltage of sampler 602 can therefore be adjusted while monitoring output data

Dout for errors without fear of collapsing the margin limits. Comparison circuit 610, an exclusive OR gate in this example, flags any mismatches between the output data and the expected data to identify errors.

[0044] In the example of Figure 6, the pseudo-random sequence of test bits applied to input terminal Din is assumed to come from an external source, such as a conventional tester. The disclosed embodiments can also be adapted to support built-in self test (BIST) or in-system testing. For example, a linked transmitter/receiver pair adapted in accordance with one embodiment can margin test the intervening link. In other embodiments, receiver 600 is modified so that register 615 or another on-chip source provides the input test sequence. In some embodiments, register 615 is extended to include additional storage elements to produce more complex pseudo-random bit sequences. In such cases, the number of outputs from register 615 to the input of sampler 602 can be the same as or different from the number of storage elements employed by the LFSR. For additional details regarding LFSRs, see "What's an LFSR," document no. SCTA036A from Texas Instruments™ (12/1996) and the Xilinx™ application note entitled "Efficient Shift Registers, LFSR Counters, and Long Pseudo-Random Sequence Generators," by Peter Alfke, XAPP 052, 7 July 1996 (Version 1.1), both of which are incorporated herein by reference.

[0045] Figure 7 depicts a receiver 700 in accordance with yet another embodiment. Figure 7 includes a number of elements that are incidental to the inventive margin-testing circuitry, and so are only touched upon briefly here. The main components of the margin-testing circuitry are highlighted using bold outlines to distinguish them from incidental features. The emphasized components include a pair of conventional samplers 705 and 710 receiving input data on

the same input terminal, Din, a pair of multiplexers 715 and 720, a pair of shift registers 725 and 730, and a data-weighting circuit 735.

[0046] In the operational mode, multiplexers 715 and 720 both select their zero input. The input data Din captured by samplers 705 and 710 is thus conveyed to respective shift registers 725 and 730. The data in shift register 730 is the output data DATA of receiver 700, and is fed back to weighting circuit 735. For equalization feedback, all or a subset of the bits stored in the plurality of storage elements that make up shift register 730 are provided to weighting circuit 735. In one embodiment, shift registers 725 and 730 each store twenty bits. Of these, five bits from register 730 are conveyed to weighting circuit 735. The selected bits and their associated weighting are optimized for a given receiver. For a detailed discussion of methods and circuits for performing such optimization, see U.S. application serial no. 10/195,129 entitled "Selectable-Tap Equalizer," by Zerbe et al., filed July 12, 2002, which is incorporated herein by reference. The details of that reference pertain to the optimization of a number of novel receivers. The margining methods and circuits disclosed herein may be of use in any systems that employ historical data to reduce ISI.

[0047] Weighting circuit 735 produces a weighted sum of a plurality of historical bits and applies this sum to input terminal Din. This is the same general function provided by the DFE ladder circuit of Figure 1, though the manner in which these weighting circuits perform this function differs significantly.

[0048] Weighting circuit 735 includes five amplifiers 745[0:4], each of which receives a bit from shift register 730. A weight-reference circuit 750 provides each amplifier 745 with a reference signal (e.g., a constant current) that

determines the weight given to the associated bit. The output terminals of amplifiers 745[0:4] are connected to input terminal Din to provide a weighted sum of five historical data values from shift register 730. A current-controlled embodiment of an amplifier 745[i] is detailed below in connection with Figure 8.

[0049] In the margin-test mode, each of multiplexers 715 and 720 selects its "one" input. The output of sampler 705 is thus conveyed to shift register 730 and the output of sampler 710 is conveyed to shift register 725. Recall that a function of the margin-test mode is to provide expected data to the input of the DFE circuitry. In this case, the expected data is the input data sampled by sampler 705 and captured in shift register 730. A voltage-control signal CV2 and timing control signal CT2 allow a tester or test personnel to alter the reference voltage and received clock RCK2 as necessary to probe the margin boundaries for sampler 710. Similar control signals CV1 and CT1 afford similar control over sampler 705 and are set to appropriate levels to ensure sampler 705 correctly captures the input data.

[0050] During a margin test, erroneous data bits from sampler 710 pass through shift register 725. Comparison circuit 755 therefore produces a logic-one error signal on line ERR. In this embodiment, it is not necessary to store expected data in advance or to provide a dedicated source of expected data. Instead, the expected data is derived from input data on terminal Din sampled by sampler 705. The sampler used to produce output data in the operational mode, sampler 710, is the same register subjected to the margin test. Testing the receive circuitry, as opposed to a replica, is advantageous because it provides a more accurate reading of the actual receive-circuitry performance. Also important, sampler 705 can be margined in a normal operating mode,

assuming that it has independent timing and voltage control relative to sampler 710. Sampler 705 can also be margin tested and the respective sample point (voltage and timing) centered in the data eye prior to margin testing sampler 710.

[0051] Receiver 700 of Figure 7 is an equalizing receiver that generates receive and equalization clock signals. The following discussion outlines various features of receiver 700. For a more detailed discussion of similar receivers, see the above-incorporated application to Zerbe et al.

[0052] In addition to the components discussed above in relation to the margin-testing methods and circuits, receiver 700 includes a CDR circuit 756 and an equalizer clock generator 759. Samplers 705 and 710 sample incoming data signal Din in response to respective receive-clock signals RCK1 and RCK2, both of which are derived from a reference clock RCLK. The samples taken by sampler 710 are shifted into register 730, where they are stored for parallel output via output bus DATA to some application logic (not shown) and to CDR circuit 756.

[0053] Receive clock signal RCLK includes multiple component clock signals, including a data clock signal and its complement for capturing even and odd phase data samples, and an edge clock signal and a complement edge clock signal for capturing edge samples (i.e., transitions of the data signal between successive data eyes). The data and edge samples are shifted into shift registers 725 and 730. Samples in register 730 are then supplied as parallel words (i.e., a data word and an edge word) to a phase control circuit 761 within CDR circuit 756. Phase control circuit 761 compares adjacent data samples (i.e., successively received data samples) within a data word to determine when data signal transitions have taken place, then compares an intervening edge sample with the preceding data sample (or succeeding data sample) to determine

whether the edge sample matches the preceding data sample or succeeding data sample. If the edge sample matches the data sample that precedes the data signal transition, then the edge clock is deemed to be early relative to the data signal transition. Conversely, if the edge sample matches the data sample that succeeds the data signal transition, then the edge clock is deemed to be late relative to the data signal transition. Depending on whether a majority of such early/late determinations indicate an early or late edge clock (i.e., there are multiple such determinations due to the fact that each edge word/data word pair includes a sequence of edge and data samples), phase control circuit 761 asserts an up signal (UP) or down signal (DN). If there is no early/late majority, neither the up signal nor the down signal is asserted.

[0054] Each of a pair of mix logic circuits 763 and 765 receives a set of phase vectors 767 (i.e., clock signals) from a reference loop circuit 769 and respective timing control signals CT1 and CT2 as noted above. The phase vectors have incrementally offset phase angles within a cycle of a reference clock signal. For example, in one embodiment the reference loop outputs a set of eight phase vectors that are offset from one another by 45 degrees (i.e., choosing an arbitrary one of the phase vectors to have a zero degree angle, the remaining seven phase vectors have phase angles of 45, 90, 135, 180, 225, 270, and 315 degrees). Mix logic circuits 763 and 765 maintain respective phase count values, each of which includes a vector-select component to select a phase-adjacent pair of the phase vectors (i.e., phase vectors that bound a phase angle equal to $360^\circ/N$, where N is the total number of phase vectors), and an interpolation component (INT). The interpolation component INT and a pair of phase vectors V1 and V2 are conveyed from each of mix logic circuits

763 and 765 to respective receive-clock mixer circuits 770 and 772. Mixer circuits 770 and 772 mix their respective pairs of phase vectors according to the interpolation component INT to generate complementary edge clock signals and complementary data clock signals that collectively constitute first and second receive-clock signals RCK1 and RCK2, which serve as input clocks for samplers 705 and 710, respectively. Timing control signals CT1 and CT2 facilitate independent control of the timing of clock signals RCK1 and RCK2.

[0055] Mix logic circuit 765 increments and decrements the phase count value in response to assertion of the up and down signals, respectively, thereby shifting the interpolation of the selected pair of phase vectors (or, if a phase vector boundary is crossed, selecting a new pair of phase vectors) to retard or advance incrementally the phase of the receive clock signal. For example, when the phase control logic 761 determines that the edge clock leads the data transition and asserts the up signal, mix logic 765 increments the phase count, thereby incrementing the interpolation component INT of the count and causing mixer 772 to incrementally increase the phase offset (retard the phase) of receive-clock signal RCK1. At some point, the phase control signal output begins to dither between assertion of the up signal and the down signal, indicating that edge clock components of the receive clock signal have become phase aligned with the edges in the incoming data signal. Mix logic 763 and mixer 770 are analogous to mix logic 765 and 772, but control the receive clock RCK1 to sampler 705. These redundant circuits are provided so the receive-clock timing to samplers 705 and 710 can be independently adjusted during margin testing.

[0056] The equalizer clock generator 759 receives the phase vectors 767 from the reference loop 769 and includes mix logic 774 and an equalizer clock mixer 776, which collectively

operate in the manner described above in connection with mix logic 765 and mixer 772. That is, mix logic 774 maintains a phase count value that is incrementally adjusted up or down in response to the up and down signals from the phase control circuit 761. The mix logic selects a phase-adjacent pair of phase vectors 767 based on a vector select component of the phase count. The mix logic then outputs the selected vectors (V1, V2) and interpolation component of the phase count (INT) to the equalizer clock mixer 776. Clock mixer 776 mixes the selected vectors in accordance with the interpolation component of the phase count to generate the equalizer clock signal EQCLK. The equalizer clock signal, which may include complementary component clock signals, is provided to weighting circuit 735 (or another type of equalization circuit) to time the output of equalizing signals onto data input terminal Din.

[0057] Figure 8 depicts an embodiment of a buffer 800 that may be used as one of amplifiers 745 in weighting circuit 735 of Figure 7 in an embodiment in which the data input Din is a two-terminal port receiving differential input signals Din and /Din. Clock signal EQCLK is also a differential signal EQCLK and /EQCLK in this embodiment.

[0058] Buffer 800 receives one of five differential feedback signals (EQDin[i] and /EQDin[i]) and the differential clock signal (EQCLK and /EQCLK) from mixer 776. Reference circuit 750 provides a reference voltage EQWi that determines the current through buffer 800, and consequently the relative weight of the selected feedback data bit.

[0059] The above-described embodiments are adapted for use in receivers of various types. The embodiment of Figure 6, for example, is applied to a receiver adapted to receive single-ended input signals, while the embodiments of Figures 7 and 8 are applied to receivers adapted to receive

complementary signals. These examples are not limiting, as these and other embodiments can be applied to receivers adapted to communicate signals in any of a number of communication schemes, including pulse-amplitude modulated (PAM) signals (e.g., 2-PAM and 4-PAM), which may be used in some embodiments to provide increased data rates.

[0060] Figure 9 depicts a receiver 900 in accordance with another embodiment. Receiver 900 is similar to receiver 700 of Figure 7, like-identified elements being the same or similar. Receiver 900 differs from receiver 700 in that receiver 900 omits multiplexer 715 and shift register 725. XOR gate 755 detects errors by comparing the data symbols from samplers 705 and 710. As in receiver 700, both samplers 705 and 710 can be margined in a normal operating mode. The operation of receiver 900 is otherwise similar to that of receiver 700.

[0061] Receivers 700 and 900, detailed in connection with respective Figures 7 and 9, do not require a predetermined pattern of data (i.e., an "expected" data pattern), and can thus be margined in the presence of the data patterns received during normal operation. The ability to detect system margins in system and without disrupting the normal flow of data enables accurate in-system margin test. In addition, receivers so equipped can be adapted to dynamically alter system parameters to maintain adequate margins.

Margin Mapping (Shmoo plots)

[0062] Figure 10A depicts a receiver 1000, a simplified version of receiver 900 of Figure 9 used to illustrate margin mapping in accordance with one embodiment. Receiver 1000 includes two samplers 1005 and 1010, an XOR gate 1015, and a "shmoo" circuit 1025. As used herein, a shmoo circuit is used to develop shmoo data, shmoo data is information that represents margin test results for a given sample point, and a

shmoo plot is a graph that represents shmoo data to illustrate how a particular margin test or series of margin tests passes or fails in response to changes in the reference voltage and reference timing. Samplers 1005 and 1010 receive the same input data Din, but have independently adjustable reference voltages RefA and RefB and reference clocks ClkA and ClkB.

[0063] Figure 10B is a diagram 1026 illustrating the relationship between each of samplers 1005 and 1010 and a data eye 1030. Each Cartesian coordinate on diagram 1026 represents a sample coordinate, the Y axis being representative of sample voltage and the X axis being representative of sample time. A data point 1035 is centered in data eye 1030 along both axes, and thus represents an ideal sample point for sampler 1005.

[0064] To perform a margin test, reference voltage RefB and reference clock ClkB are adjusted along their respective Y and X axes to sample data symbols at each coordinate one or more times to probe the boundaries of eye 1030. Margins are detected when XOR gate 1015 produces a logic one, indicating that sampler 1010 produced different data than sampler 1005. Shmoo circuit 1025 correlates errors with the respective reference voltage RefB and clock signal ClkB for sampler 1010 and stores the resulting X-Y coordinates. Care should be taken to ensure proper clock-domain crossing of the two reference clocks ClkA and ClkB to prevent data samplers 1005 and 1010 from sampling different data eyes (e.g., to prevent respective samplers from sampling different ones of two successive data symbols). Signals RefB and ClkB can be interchanged with respective signals RefA and ClkA in Figure 10B to margin sampler 1010. Methods and circuits for adjusting clock phases and reference voltages are well known in the art, and are therefore omitted here for brevity.

[0065] Figure 10C depicts a shmoo plot 1050 graphically depicting an illustrative margin test in accordance with one

embodiment. During margin test, reference voltage RefB and reference clock ClkB are adjusted to sample incoming data at each voltage/time square (sample point) represented in Figure 10C. The number of errors encountered over a fixed time is then recorded for each sample coordinate. The resulting plot for a given receiver will bear a resemblance to plot 1050, though will typically be less uniform than this illustration.

[0066] Plot 1050 can be used in a number of ways. Returning to Figure 10B, for example, data point 1035 is depicted in the center of eye 1030, an ideal circumstance. Plot 1050 can be used to precisely locate the true center of eye 1030. Once this center is known, reference voltage RefA and reference clock ClkA can be adjusted as needed to maximize the margins for sampler 1005.

[0067] Plot 1050 can also be used to establish different margins depending upon the allowable bit-error rate (BER) for the communication channel of interest. Different communication schemes afford different levels of error tolerance. Communications channels can therefore be optimized using margin data gathered in the manner depicted in Figure 10C. For example, an error-intolerant communication scheme might require the zero-error margin, whereas a more tolerant scheme might be afforded the larger margin associated with a small number of errors per unit time.

Adaptive Margining

[0068] Some embodiments detect and maintain margins without storing the shmoo data graphically depicted in Figure 10C. One or more additional samplers can be used to probe the margins periodically or dynamically, and the sampler used to obtain the sampled data can be adjusted accordingly. In one embodiment, for example, the reference voltage and clock of the sampler used to obtain the sampled data are adjusted in

response to perceived errors to maintain maximum margins. With reference to Figure 10A, sampler 1010 can periodically probe the high and low voltage margins and then set reference voltage RefA between them. With reference voltage RefA thus centered, the process can be repeated, this time adjusting the phase of reference clock ClkB to detect the timing margins. The phase of reference clock ClkA can then be aligned in eye 1030. In other embodiments, additional samplers can simultaneously probe different margins of eye 1030. Dynamic margining systems in accordance with these embodiments thus automatically account for time-variant system parameters (e.g., temperature and supply-voltage).

[0069] Figure 11 details an embodiment of shmoo circuit 1025 of Figure 10A. Shmoo circuit 1025 includes a pair of flip-flops 1100 and 1105. Flip-flop 1100 synchronizes error signal Err with a clock signal Clk. Flip-flop 1105, a ones detector, produces a logic-one output signal OUT in response to any logic ones received from flip-flop 1100. In operation, both flip-flops are reset to zero and error signal Err is monitored for a desired number of data samples at a given timing/voltage setting. Flip-flop 1100 captures any logic-one error signals Err, and ones detector 1105 transitions to logic one and remains there in response to any logic ones from flip-flop 1100. A logic one output signal OUT is therefore indicative of one or more error signals received in the sample period. In other embodiments, flip-flop 1105 is replaced with a counter that counts the number of captured errors for a given period. The number and duration of the sample periods can be changed as desired.

[0070] Figure 12 details a double-data-rate (DDR) receiver 1200 in accordance with another embodiment adapted to accommodate margin shmooing. Receiver 1200 includes four data samplers 1205-1208 timed to an odd-phase clock Clk_O, four

respective flip-flops 1210 timed to an even-phase clock Clk_E, three error-detecting XOR gates 1215, a multiplexer 1220, error-capturing logic 1225, and shmoo control logic 1230. An external tester (not shown) issues test instructions and receives margin-test results via a test-access port TAP. In another embodiment, the outputs from the three flip-flops 1210 following samplers 1205, 1206, and 1207 connect directly to corresponding inputs of multiplexer 1220. A single XOR gate on the output side of multiplexer 1220 then compares the selected sampler output signal with the output from sampler 1208.

[0071] As is conventional, DDR receivers receive data on two clock phases: an odd clock phase Clk_O and an even clock phase Clk_E. Receiver 1200 represents the portion of a DDR receiver that captures incoming data using the odd clock phase Clk_O. Signals specific to only one of the clock phases are indicated by the suffix "_E" or "_O" to designate an even or odd phase, respectively. Samplers 1205, 1206, and 1207 are portions of the "odd" circuitry. Similar samplers are provided for the even circuitry but are omitted here for brevity. The odd and even clock phases of a DDR high-speed serial input signal can be shmooed separately or in parallel.

[0072] Receiver 1200 enters a shmoo mode at the direction of the external tester. Shmoo select signals Shm[1:0] then cause multiplexer 1220 to connect the output of one of XOR gates 1215 to the input of error-capturing logic 1225. The following example assumes multiplexer 1220 selects error signal Err1 to perform margin tests on sampler 1205. Margin tests for the remaining samplers 1206 and 1207 are identical.

[0073] The external tester initiates a shmoo test cycle by issuing a rising edge on terminal Start. In response, control logic 1230 forces a signal Running high and resets a ones detector 1235 within error-capturing logic 1225 by asserting a reset signal RST. When signal Start goes low, control logic

1230 enables ones detector 1235 for a specified number of data clock cycles--the "shmoo-enable interval"--by asserting an enable signal EN. When period-select signal PeriodSel is zero, the number of data clock cycles in the shmoo-enable interval is 160 (320 symbol periods). When signal PeriodSel is one, the number of data clock cycles in the shmoo-enable interval is 128 (256 symbol periods).

[0074] The lower-most sampler 1208, in response to control signals from the external tester, shmooes the margins for the sampler 1205 selected by multiplexer 1220. The shmooing process is similar to that described above in connection with Figures 10A, 10B, and 10C. The process employed by receiver 1200 differs slightly, however, in that receiver 1200 takes advantage of the presence of even clock Clk_E and flip-flops 1210 to retime the input signals to XOR gates 1215. Even clock Clk_E is 180 degrees out of phase with respect to odd clock Clk_O. Clock signal ClkB can therefore be varied up to 90 degrees forward or backward with respect to odd clock Clk_O without fear of sampling different data symbols with the selected sampler 1205 and sampler 1208.

[0075] The upper-most XOR gate 1215 produces a logic one if, during the shmoo-enable interval, one or more bits from sampler 1205 mismatches the corresponding bit from sampler 1208. A flip-flop 1240 captures and conveys this logic one to ones detector 1235. At the end of the shmoo-enable interval, controller 1230 brings signal Running low and holds that state of signal Err_O. A logic one error signal Err_O indicates to the tester that at least one mismatch occurred during the shmoo-enable interval, whereas a logic zero indicates the absence of mismatches.

[0076] The shmoo interval can be repeated a number of times, each time adjusting at least one of reference voltage RefD and clock CLKB, to probe the margins of input data Din. A

shmoo plot similar to that of Figure 10B can thus be developed for sampler 1205. This process can then be repeated for the remaining samplers.

[0077] Control logic 1230 does not interfere with the normal operation of receiver 1200, so shmooing can be performed for any type of input data Din. Also advantageous, receiver 1200 allows for the capture of real data eyes under various operating conditions, and can be used to perform in-system margin tests.

[0078] Other embodiments repeat the process a number of times for each of an array of voltage/time data points to derive margin statistics that relate the probability of an error for various sample points within a given data eye. Still other embodiments replace ones detector 1235 with a counter that issues an error sum count for each shmoo-enable interval.

[0079] In one embodiment, receiver 1200 samples four-level, pulse-amplitude-modulated (4-PAM) signals presented on terminal Din, in which case each of samplers 1205-1207 samples the input data symbols using a different reference voltage level. In general, the methods and circuits described herein can be applied to N-PAM signaling schemes, where N is at least two. Such systems typically include N-1 samplers for each data input node.

[0080] Figure 13 depicts a receiver 1300 that supports error filtering in accordance with another embodiment. Receiver 1300 is similar to receiver 1000 of Figure 10A, like-numbered elements being the same or similar. Receiver 1300 differs from receiver 1000 in that receiver 1300 includes data filter 1305 that allows receiver 1300 to shmoo particular data patterns. This is a benefit, as a receiver's margin may differ for different data patterns, due to ISI for example. Data filter 1305 allows receiver 1300 to perform pattern-specific margin tests to better characterize receiver performance.

[0081] Data filter 1305 includes a series of N data registers 1310 that provide a sequence of data samples Dout to a pattern-matching circuit 1315. In this case N is three, but N may be more or fewer. Data filter 1305 also includes a series of M (e.g., two) error registers 1320 that convey a sequence of error samples to an input of an AND gate 1325. AND gate 1325 only passes the error signals from registers 1320 if pattern-matching circuit 1315 asserts a error-valid signal ErrVal on the other input of AND gate 1325. Pattern-matching circuit 1315 asserts signal ErrVal only if the pattern presented by registers 1310 matches some predetermined pattern or patterns stored in pattern-matching circuit 1315. In one embodiment external test circuitry (not shown) controls the patterns provided by matching circuit 1315. Other embodiments support in-system testing with one or more patterns provided internally (e.g., on the same semiconductor chip).

[0082] Some of the foregoing embodiments employ an additional sampler to probe the margins of a given data input. Some receiver architectures already include the requisite additional sampler, to support additional signaling modes, for example. Other embodiments may be adapted to include one or more additional "monitor" samplers.

[0083] While the present invention has been described in connection with specific embodiments, variations of these embodiments will be obvious to those of ordinary skill in the art. Moreover, unless otherwise defined, terminals, lines, conductors, and traces that carry a given signal fall under the umbrella term "node." In general, the choice of a given description of a circuit node is a matter of style, and is not limiting. Likewise, the term "connected" is not limiting unless otherwise defined. Some components are shown directly connected to one another while others are shown connected via intermediate components. In each instance, the method of

interconnection establishes some desired electrical communication between two or more circuit nodes, or terminals. Such communication may often be accomplished using a number of circuit configurations, as will be understood by those of skill in the art. Furthermore, only those claims specifically reciting "means for" or "step for" should be construed in the manner required under the sixth paragraph of 35 U.S.C. section 112. Therefore, the spirit and scope of the appended claims should not be limited to the foregoing description.
